Abstract: Contrast-enhanced ultrasound (CEUS) has become more recognized in the diagnosis of hepatocellular carcinoma (HCC). Fat containing HCC often presents as hyper-echoic in gray scale ultrasound and confuses the diagnosis. Here we showed a case of fat containing HCC which was diagnosed by CEUS with Sonazoid, and its histopathologic features, immunohistochemical profile, surgical treatment, patient’s follow up information were also presented.

Key words: Hepatocellular carcinoma; Sonazoid; Contrast agent; Fat-containing

Advanced Ultrasound in Diagnosis and Therapy 2021;02:098-101 DOI: 10.37015/AUDT.2021.200003

The high incidence of HCC and its threat to health is a global burden. Identification of HCC in an early stage is extremely important since this kind of patient can receive curative treatment before the tumor spreading; and then the quality of life can be improved and the economic cost of society can be reduced [1]. With the development of imaging techniques such as contrast enhanced ultrasound (CEUS) [2], most HCC can be correctly diagnosed before operation, due to their typical enhancement pattern: hyper-enhancement in the arterial phase followed by mile-late wash-out in the portal phase and delayed phase, which is different from most benign lesions.

However, some well-differentiated HCC show iso-enhancement at delayed phase and have been reported to have various enhancement patterns [3], which depends on the degree of carcinogenesis including the increase of arterial flow and decrease of portal supplying [4]. And if they contain fat, diagnosis can be even more challenging since fat containing HCC often presents as hyperechoic on gray scale ultrasound, which is different from common HCC [5], and the CEUS manifestation of this kind of HCC is always atypical. The reason might be that fat containing was usually found in the well-differentiated HCC, and with the increased histologic grade, fat containing became infrequent [6].

Sonazoid (Daiichi Sankyo, Tokyo, Japan) is a novel ultrasound contrast agent and it was officially launched in China in March 2019. It provides hepatic parenchyma-specific contrast images because of its accumulation in the Kupffer cells of the liver [7]. Whether Sonazoid-CEUS can provide meaningful diagnostic information for fat containing HCC needs to be investigated.

This report is the first time to describe the Sonazoid-CEUS features of fat-containing HCC. The low staining of the lesion in the Kupffer phase provided valid information and increased the confidence in the diagnosis of HCC.

Case Report

Chief complaints

A 36-year-old male complained of liver cirrhosis and focal liver mass for 6 months during regular gray scale ultrasound follow-up, without any obvious positive symptoms and signs when he presented at our hospital. A gray scale ultrasound showed a 2 cm solid hypoechoic mass in the right lobe of the liver. A biopsy result of the mass showed typical features of well-differentiated HCC; however, no fat containing was detected.

Contrast-enhanced ultrasound (CEUS) was then performed with Sonazoid (2 mL, 2.4 MPA). The arterial phase showed a hyper-enhancement, followed by a mild late wash-out in the portal and delayed phases. The lesion was found to be iso-enhanced in the Kupffer phase. The low staining of the lesion in the Kupffer phase provided valid information and increased the confidence in the diagnosis of HCC.

Surgical treatment

The patient underwent a right liver lobectomy. The postoperative course was uneventful and the patient was discharged on the 7th postoperative day. The histopathologic features of the resected specimen were consistent with the typical features of well-differentiated HCC.

Patient’s follow up information

The patient was followed up for 1 year after surgery. During the follow up period, he had no evidence of recurrence or metastasis.

Conclusion

Sonazoid-CEUS is a valuable tool in the diagnosis of fat containing HCC. The low staining of the lesion in the Kupffer phase provided valid information and increased the confidence in the diagnosis of HCC.
hospital. Local ultrasound report showed liver cirrhosis, splenomegaly and liver mass suspected as HCC.

**History of present illness**

The patient was diagnosed with hepatitis B virus (HBV) infection for 20 years, and two years ago the patient visited to our hospital for routine follow-up, laboratory examinations showed that the value of HBV-DN was $3.82 \times 10^7$ IU/mL, the content of hepatitis B surface antigen (HBsAg) was 4520.35 IU/mL, and the liver function index was normal with 40 U/L Alanine aminotransferase (ALT) and 35 U/L Aspartate transaminase (AST); liver ultrasound examination showed no liver cirrhosis or focal liver lesions (FLLs), and the patient began to take Entecavir capsules 0.5 mg, Qd regularly. Six months ago, the follow-up examinations showed that the value of ALT and AST was 72 U/L and 68 U/L respectively, HBV-DN was $2.55 \times 10^7$ IU/mL, HBsAg was 1973.27 IU/mL. The liver ultrasound showed liver cirrhosis, splenomegaly, multiple regenerating nodules (RNs) with a maximum diameter of 1.3 cm and the patient continued to be followed up regularly. The latest examination was two days ago and the results showed that the value of ALT and AST was 55 U/L and 51 U/L respectively, HBV-DN was $1.89 \times 10^4$ IU/mL, HBsAg was 1786.05 IU/mL. The value of Alpha fetoprotein (AFP) was 208.1 ng/mL, the liver ultrasound showed liver cirrhosis, splenomegaly, multiple FLLs and the largest lesion with a maximum diameter of 3.0 cm which was suspected as HCC (Fig. 1).

![Figure 1](image-url)  
**Figure 1** Gray scale ultrasound images of the patient’s liver 2 years ago (A), 6 months ago (B); 2 days ago (C).

**Family history**

The patient’s mother had HBV related liver cirrhosis and three sisters had chronic hepatitis B, but none of them had a history of HCC.

**Physical examination**

The patient’s basic information showed no skin or scleral yellow staining, but several spider nevus can be seen in the anterior part of the neck and double forearms.

**Laboratory examination**

Blood analysis showed white blood cells at $3.4 \times 10^9$/L, with light decrease of neutrophilic granulocyte percentage at 40.1% and increase of lymphocyte percentage at 47.8%. The value of ALT and AST was 41 U/L and 39 U/L respectively, HBV-DN was $2.67 \times 10^4$ IU/mL, HBsAg was 1796.77 /mL. The partial thromboplastin, prothrombin times and D-dimers were normal. The serum hepatic fibrosis index increased including Urine collagen IV at 167.92 ng/mL, Urine Laminin at 117.14 ng/mL, and serum hyaluronic acid at 270.77 ng/mL and type III Procollagen n-terminal peptide at 15.08 ng/mL. The value of tumor abnormal protein (TAP) and AFP were 127 MAU/mL and 235 ng/mL respectively.

**Imaging examination**

All ultrasound examinations were performed with a MyLab Classic system (Easote, Italy) equipped with a convex probe (3.5 MHz). Gray scale ultrasound showed a hyper-echoic lesion with clear margin and round shape in the segment 7, Doppler Flow Imaging (CDFI) showed no obvious flow signal in the lesion. The mechanical index (MI) was set at 0.20 for the Sonazoid CEUS examination. Sonazoid was used with a recommended dose of 0.015 mL/kg and injected into the cubital vein. Sonazoid-CEUS showed homogenous hyper-enhancement of the lesion in arterial phase and prolonged iso-enhanced with the peripheral parenchyma in the portal and delayed vascular phase. Post-vascular phase observation showed a defect of perfluorobutane contrast agent of the lesion in Kupffer phase (Fig. 2), and HCC was suspected.

**Final diagnosis and treatment**

Considering the low uptake of Sonazoid in Kupffer phase by the lesion and the fact that the patient had 20 years’ HBV infection history and liver cirrhosis, the patient received a liver biopsy (LB) for the lesion and after LB, radiofrequency ablation (RFA) was performed.
Outcome and follow-up

The pathological reports showed the lesion was a well-differentiated HCC and immunochemistry staining confirmed it including the presence of hepatocyte and GPC-3 and absence of CK7, CK19 and CD68 (Fig. 3). The patient was discharged two days after RFA and one month later, the patient came to our hospital for reexamination with CE-MRI and results showed complete remission of the lesion.

Figure 2  The images of Sonazoid-CEUS. (A) Gray scale ultrasound (left) showed a hyper-echoic, clear margin, round shape lesion in Segment VII; (B-D) the lesion was hyper-enhanced in the arterial phase with consistent iso-enhanced in the portal and late phase and cannot be distinguished; (E) it showed a defect of contrast agent in Kupffer phase (arrow).

Discussion

In the background of liver cirrhosis, a lesion containing fat was special but easily overlooked for HCC, and the reason for fat developed in HCC is still unknown. Most researches supported the relative ischemia theory during the process of reconstruction of blood supply ratio between hepatic artery and portal vein, so for the advanced HCC lesions especially large ones with established arterial system, containing fat was rare [5]. And due to the establishment of unpaired arteries, the contrast enhanced features of advanced HCC lesions are hyper-enhancement in the arterial phase and quickly wash out in the portal phase.

However, what often confused us was well-differentiated HCC which might show sustained enhancement during the portal phase and delayed phase, and if this type of HCC also contains fat, then it will become increasingly difficult to be correctly diagnosed. Because some benign focal liver lesions (FLLs) like hepatic Angiomyolipoma (HAML), focal nodular hyperplasia (FNH) can also contain fat. Besides, they sometimes shared similar imaging characteristics with the case in this study: hyper-enhanced in arterial phase and consistent hyper/iso-enhanced in the portal phase and delayed phase.

Fortunately, with the application of Sonazoid, several studies had confirmed the iso-uptake of Sonazoid contrast agent at the Kupffer phase of HAML and FNH, compared with peripheral liver parenchyma [8,9]. Meanwhile, there was pathological evidence supporting that CD68 staining positive cells were found [9], which means the existence of Kupffer cells or migrating macrophages in these two kinds of FLLs. And the application of Sonazoid, CD68 positive cell-specific ultrasound contrast agent, enables the preoperative imaging diagnosis of FLLs to be accurately to the cellular level. And the low Sonazoid-uptake in Kupffer phase could be a promising feature for differentiating HCC from some benign kinds of FLLs.
Conclusion

We have presented a case of fat containing HCC and described the Sonazoid-CEUS features here, which might be helpful in the diagnosis of a hyper-echoic fat containing HCC.
